ABSTRACT

Rotational transition lines of CO play a major role in molecular radio astronomy as a mass tracer and in particular in the study of star formation and Galactic structure. Although a wealth of data exists for the Galactic plane and some well-known molecular clouds, there is no available high sensitivity all-sky survey of CO emission to date. Such all-sky surveys can be constructed using the Planck HFI data because the three lowest CO rotational transition lines at 115, 230 and 345 GHz significantly contribute to the signal of the 100, 217 and 353 GHz HFI channels, respectively. Two different component separation methods are used to extract the CO maps from Planck HFI data. The maps obtained are compared to each other to identify different CO features. From these quality checks the best CO maps, in terms of signal to noise ratio and/or residual contamination by other emission, are selected. Three different sets of velocity-integrated CO emission maps are produced with different trade-offs between signal-to-noise, angular resolution, and reliability. Maps for the CO J = 1 → 0, J = 2 → 1, and J = 3 → 2 rotational transitions are presented and described in detail. They are shown to be fully compatible with previous surveys of parts of the Galactic plane as well as with undersampled surveys of the high latitude sky. The Planck HFI velocity-integrated CO maps for the J = 1 → 0, J = 2 → 1, and J = 3 → 2 rotational transitions provide a major all-sky view of the Galactic CO population. The maps also are of great interest to monitor potential CO contamination of the Planck studies of the cosmological microwave background.

1. Introduction

This paper, one of a set associated with the 2013 release of data from the Planck mission (Planck Collaboration I 2014), describes the construction and validation of full-sky carbon monoxide (CO) maps from Planck data.

The interstellar medium (ISM) represents about 10–15% of the total mass of the Milky Way. The neutral part of the ISM is a mixture of atomic and molecular gas, the latter containing around 50% of its mass whilst filling only a tiny fraction of the volume (see Ferrière 2001; Cox 2005, for a general introduction and review). The cold neutral gas is confined close to the Galactic disk mid-plane (about 100 pc scale height), in clouds with varying molecular-to-atomic ratios. Molecular clouds are the sites of star formation, and as such, play a pivotal role in the interstellar matter cycle. Giant molecular clouds (GMCs) are the largest self-gravitating structures in spiral galaxies such as the Milky Way, and are also the most massive entities, reaching several times 10^6 M⊙. Molecular clouds were discovered via the rotational emission line J = 1 → 0 of carbon monoxide in its fundamental electronic and vibrational levels (Wilson et al. 1970; Penzias et al. 1972). Contrary to the atomic component of the neutral ISM, which is directly observable via the spin-flip HI 21 cm line, the bulk of molecular hydrogen is not directly observable in molecular clouds. Because CO is abundant, easily excited by collisions with H₂, and easily observable from the ground, it is considered a good tracer of the cold molecular component of the ISM. It is also a dominant coolant of molecular gas. The ability to detect the CO J = 1 → 0 line from the ground allows large surveys to be performed (Dame et al. 2001; Dame & Thaddeus 2004; Wilson 2005), leading to observational evidence that the molecular gas is structured in clouds that are turbulent and harbour the formation of all stars in the Galaxy. The astrophysical importance of carbon monoxide can hardly be over-emphasized.

Large-scale surveys the J = 1 → 0 line of 12CO, but also of 13CO and C₁⁰O isotopologues, have been carried out with meter-sized radio telescopes, mostly through the fundamental rotational transition. The most complete CO(1 → 0) survey is that of Dame et al. (2001), which covers the Milky Way at Galactic latitudes |b| ≤ 30°, with an effective spatial resolution of 0.14° in most regions. CO and isotopologues were observed with the 4 m NANTEN telescope providing spectral maps at slightly higher spatial resolution, towards specific GMCs (Mizuno & Fukui 2004). In addition, there exist a wealth of smaller CO(1 → 0) line surveys, such as for example in Orion and Monoceros (Wilson et al. 2005; Magnani et al. 1985; Hartmann et al. 1998; Magnani et al. 2000) have revealed the existence of CO emission at Galactic latitudes up to 55°. However, these high-latitude observations provide only a limited view of the |b| > 30° sky.

High-resolution full-sky surveys of higher J CO transitions have never been carried out, essentially because these are much more time consuming than J = 1 → 0 observations (atmospheric transmission is poorer, and higher-spatial resolution requires finer spatial sampling). High-J lines are expected to probe molecular gas with stronger excitation conditions (high density and/or warmer) better than the J = 1 → 0 line. Combined with

\[1\] Planck (http://www.esa.int/Planck) is a project of the European Space Agency (ESA) with instruments provided by two scientific consortia funded by ESA member states (in particular the lead countries France and Italy), with contributions from NASA (USA) and telescope reflectors provided by a collaboration between ESA and a scientific consortium led and funded by Denmark.

Fig. 1. The average spectral response for each of the HFI frequency bands. The vertical dashed lines represent the first nine ¹³CO rotational transitions assuming zero velocity.

CO(1 → 0), observations of J ≥ 2 lines therefore provide constraints on the physical conditions in the molecular ISM. Only specific regions have been mapped in the J = 2 → 1 CO line, e.g., the Galactic Centre region has been observed by Sawada et al. (2001). Maps of W3 and W5 (Bieging et al. 2010; Bieging & Peters 2011) are also available. For the J = 3 → 2 line, the Galactic centre has been observed by Oka et al. (2012), Orion by Ikeda et al. (1999) and W3 by Bieging et al. (2010).

The ESA Planck satellite was launched on 14 May 2009 in order to (primarily) measure with unprecedented precision the temperature and polarization anisotropies of the cosmological microwave background (CMB). It observed the sky in nine frequency bands covering 30–857 GHz with high sensitivity and angular resolution from 31′ to 5′. The Low Frequency Instrument (LFI; Mandolesi et al. 2010; Bersanelli et al. 2010; Mennella et al. 2011) covers the 30, 44, and 70 GHz bands with amplifiers cooled to 20 K. The High Frequency Instrument (HFI; Lamarre et al. 2010; Planck HFI Core Team 2011a) covers the 100, 143, 217, 353, 545, and 857 GHz bands with bolometers cooled down to 0.1 K. Planck’s sensitivity, angular resolution, and frequency coverage make it a powerful instrument for Galactic and extragalactic astrophysics as well as cosmology (Planck Collaboration I 2014).

The first nine CO rotational transition lines lie within the spectral bands of the HFI instrument. Of these, the first three, J = 1 → 0, J = 2 → 1, and J = 3 → 2 at 115, 230 and 345 GHz, respectively, present the largest transmission coefficients making them a significant component in the Planck intensity maps. In this paper, we extract full-sky CO maps for these three lines from the LFI and HFI data using component separation methods. The Planck intensity maps are presented in Sect. 2. In Sect. 3, we provide a brief description of HFI bandpasses and estimate the CO transmission coefficients for the most important rotational lines. Specifically tailored component separation methods for CO extraction in the Planck maps are detailed in Sect. 4. The Planck CO maps obtained using the above methods are presented in Sect. 5. Uncertainties and contamination from other astrophysical emission on those maps are discussed in Sect. 6. The internal validation of the Planck CO maps is presented in Sect. 7. Detailed comparisons to existing external CO surveys are presented in Sect. 8. Finally, we discuss the results and draw conclusions in Sect. 9.
2. Planck data

This paper is based on the first 15.5 months of Planck survey mission (two full-sky surveys) and uses the full-sky maps of the nine Planck frequency bands, and also the 100, 217 and 353 GHz full-sky maps made of individual bolometer data. These maps are provided in HEALPix\(^2\) pixelization (Görski et al. 2005) with N\(_\text{side} = 2048\) at full resolution. We refer to Planck Collaboration II (2014), Planck Collaboration V (2014), Planck Collaboration VI (2014), Planck Collaboration X (2014), Planck Collaboration VIII (2014) for the generic scheme of TOI processing and map-making, as well as for calibration. These Planck maps are given in K\(_\text{CMB}\) units, i.e., in temperature units referred to the CMB blackbody spectrum. The scanning strategy of Planck consists of circles on the sky, with radius of about 85°, corresponding to different positions of the satellite spin axis. The latter is changed by 2/5 every 40 to 60 min in order to cover the full sky in about seven months. The data set acquired for each position of the satellite spin axis is called a ring and consists of 40 to 60 observations of the same circle on the sky. Thus, a noise map can be obtained for each frequency band or bolometer map from the half difference of the maps of the first and second half of the rings. The resulting noise maps are basically free from astrophysical emission and thus a good representation of the statistical instrumental noise and systematic errors. In the following we assume that the beam pattern of the maps can be well represented by effective circular Gaussians with FWHM of 32/24, 27/01, 13/25, 9/65, 7/25, 4/99, 4/82, 4/68, and 4/33 at 30, 44, 70, 100, 143, 217, 353, 545, and 857 GHz, respectively (Planck Collaboration IV 2014; Planck Collaboration VII 2014).

3. CO contribution in the Planck HFI channels

3.1. HFI spectral response and CO emission

In order to isolate the narrow CO features from the other sources of sky emission (e.g., CMB, dust, free-free, etc.), precise knowledge of the instrument spectral response as a function of frequency is required. The original spectral resolution requirement for the response of a given HFI detector was about 3 GHz; this corresponds to a velocity resolution of around 8000 km s\(^{-1}\) for the CO(1 → 0) line. As HFI does not have the ability to measure spectral response within a frequency band during flight, ground-based Fourier Transform Spectrometer (FTS) measurements provide the authoritative data on the HFI spectral transmission. With good S/N, spectral information can be inferred to a fraction (i.e., approximately 1/10th) of a spectral resolution element (Spencer et al. 2010). Thus, the pre-flight calibration FTS measurements (Pajot et al. 2010), which were carried out at a spectral resolution of about 0.6 GHz (better by a factor of 5 than the requirement), may be used to estimate the spectral response at a resolution equivalent to 150 km s\(^{-1}\) for the CO(1 → 0) line. For spectral regions near CO rotational transitions, therefore, the spectral response was oversampled by a factor of around 10 using an interpolation based on the instrument line shape of the FTS. Table 1 lists the relevant CO transitions, and the frequency ranges over which the HFI spectral response was oversampled (Planck Collaboration IX 2014). The oversampling ranges were extended to include all of the common CO isotopologues.

3.2. Spectral band CO conversion coefficients

The Planck sky maps are calibrated in CMB temperature units K\(_\text{CMB}\) so that CMB anisotropies have a constant spectrum across frequencies. The CO velocity-integrated emission (VIE) is in general expressed as the product of Rayleigh-Jeans temperature and spectral line width in velocity units, i.e., K km s\(^{-1}\). In practice, to evaluate the contribution of the CO emission to the Planck maps we need to convert from the latter CO-based units to the former CMB-based ones accounting for the spectral bandpass of each of the Planck detectors. We can write the CO emission contribution to the map of detector \(b\) as

\[
M_{\text{CO},b}[\text{K}_{\text{CMB}}] = F_{\text{CO},b} \times M_{\text{CO}} \left[ \text{K km s}^{-1} \right],
\]

where \(F_{\text{CO},b}\) is the CO conversion coefficient. These CO conversion coefficients between CO brightness temperature and CMB temperature can be determined using the measured spectral bandpass of the detectors following Planck Collaboration IX (2014):

\[
F_{\text{BP,CO},b} = \frac{\int dv H_v^b f_{\text{CO}}}{\int dv H_v^c f_{\text{CMB}}} = \frac{\int dv H_v^c f_{\text{CMB}}}{\int dv H_v^c f_{\text{CO}}} \quad (2)
\]

where \(H_v^b\) is the spectral transmission of bolometer \(b\) at frequency \(v\), and \(f_{\text{CO}}\) and \(f_{\text{CMB}}\) are the CO and CMB intensities, respectively. The integral is performed across the extension of the spectral band.

For the lowest rotational CO transitions a Doppler shifted line profile may be assumed with \(v = v_{\text{CMB}}(1 + v/c)^{-1} \approx v_{\text{CMB}}(1 - v/c)\) for \(v \ll c\). As the CO transitions occur at discrete frequencies, with a Doppler line-width much less than the transition frequency (about \(10^3\) Hz cf. \(10^{11}\) Hz), and much narrower than the available knowledge of the HFI detector spectral response (about \(10^8\) Hz), the velocity integration may be approximated by approximately a delta-function distribution at \(v_{\text{CMB}}\), i.e., \(\delta_{\text{CMB}}\).

Bandpass CO conversion coefficients for the first three CO transitions were determined using the above relation (see Planck Collaboration IX 2014); similar data are available for the individual HFI detectors and for the other transitions within HFI bands. Table 2 (first column) lists the relative values of these CO conversion coefficients for the \(^{12}\)CO isotopologue (averaged for each \(a\) and \(b\) pair of polarized bolometers) normalized to the average transmission of all bolometers in the band (this format is chosen to ease comparison to the sky-calibrated CO conversion coefficients; see next section). To recover the physical CO conversion coefficients, values in the table must be multiplied by

Table 1. Rotational \(^{12}\)CO transitions within the HFI bands and oversampled regions.
the average of $^{12}\text{CO}$ conversion coefficients, namely, $1.42 \times 10^{-5} \text{K}_{\text{CMB}}/(\text{K km s}^{-1})$ at 100 GHz, $4.50 \times 10^{-5} \text{K}_{\text{CMB}}/(\text{K km s}^{-1})$ at 217 GHz and $17.37 \times 10^{-5} \text{K}_{\text{CMB}}/(\text{K km s}^{-1})$ at 353 GHz.

As will be described in Sect. 6.2.2, the $^{13}\text{CO}$ isotopologue may contribute to the Planck CO maps. The CO conversion coefficients of $^{12}\text{CO}$ are computed in the same way as described for $^{12}\text{CO}$, but for the $^{13}\text{CO}$ transitions at $v^{[1]}_0 = 110.2 \text{GHz}$, $v^{[2]}_0 = 220.40 \text{GHz}$, and $v^{[3]}_0 = 330.6 \text{GHz}$. The average CO conversion coefficients over all bolometers in the 100, 217, and 353 GHz channels are $1.62 \times 10^{-5} \text{K}_{\text{CMB}}/(\text{K km s}^{-1})$, $3.63 \times 10^{-5} \text{K}_{\text{CMB}}/(\text{K km s}^{-1})$, and $13.0 \times 10^{-5} \text{K}_{\text{CMB}}/(\text{K km s}^{-1})$, respectively.

### 3.3. Sky-calibrated CO conversion coefficients

In the following sections we will use CO conversion coefficients to extract maps of the CO emission from the Planck frequency maps. For this purpose, we need an accurate estimates of the relative CO conversion coefficients between bolometers (see Appendix B for further discussions). The bandpass CO conversion coefficients present two main problems. First, the estimation of the spectral band transmissions of each of the bolometers may be affected by systematic errors as we are dealing with narrow lines. Indeed, HFI bandpasses are not sampled to a sufficient resolution to allow for a satisfactory CO extraction using these coefficients and then need to be interpolated as discussed above. Second, both $^{12}\text{CO}$ and $^{13}\text{CO}$ (and other isotopologues) are present in the Planck maps. The emission from $^{12}\text{CO}$ is spatially correlated to that of $^{13}\text{CO}$ with a varying ratio across the sky and we cannot discriminate between the two. Thus, an accurate determination of the relative CO conversion coefficients

between bolometers of the same Planck channel is difficult when using bandpass information only.

A way around these issues has been found in estimating the CO conversion coefficients directly from sky measurements of well-known molecular clouds. For these regions, we can assume – to first order – that the map of the sky emission for a detector is a linear combination of CO and thermal dust emissions weighted by the CO and thermal dust conversion coefficients of the detector. Thus, using an external CO emission template, $P_{\text{CO}}$, obtained from the Dame et al. (2001) $^{12}\text{CO}$ $J = 1 \rightarrow 0$ survey and a dust emission template, the 545 GHz Planck-HFI channel map (in K$_{\text{CMB}}$ units), $P_d$, it is possible to determine sky-calibrated CO and dust transmission coefficients $F_{\text{sky,CO}}^b$ and $F_{\text{sky,dust}}^b$ of bolometer $b$. Notice that we implicitly assume here perfect spatial correlation between the $^{12}\text{CO}$ and $^{13}\text{CO}$ components.
Neglecting other astrophysical components (i.e., CMB, free-free, synchrotron, anomalous microwave emission and point sources), we perform a simple linear fit between each bolometer map $M_b$ in the native units ($K_{\text{CMB}}$) and the CO and dust templates:

$$M_b = F_{\text{fit,CO}}^{\text{fit}} P_{\text{CO}} + F_{\text{dust},b}^{\text{fit}} P_d,$$  \hfill (3)

where $F_{\text{fit,CO}}^{\text{fit}}$ and $F_{\text{dust},b}^{\text{fit}}$ are the results of the linear regression. To avoid contamination from dust polarization emission we combine the maps of pairs of polarized bolometers into a single map and a single CO conversion coefficient is computed for the pair of detectors.

Due to the spatial correlation between the CO and dust emission, we expect the CO conversion coefficients, $F_{\text{fit,CO}}^{\text{fit}}$, to be affected by dust contamination and so biased. We simply assume here that the estimated CO conversion coefficient can be expressed as $F_{\text{fit,CO}}^{\text{fit}} = \alpha F_{\text{sky,CO}}^{\text{fit}} + \beta$ corresponding to an offset and a shift in total amplitude. However, we will assume that thermal dust conversion coefficients are not affected by CO contamination significantly and thus $F_{\text{dust},b}^{\text{fit}} = F_{\text{dust},b}^{\text{fit}}$.

To compute $\alpha$ and $\beta$ we solve the following system of equations. First, we construct dust-weighted bolometer (or bolometer pair) maps. Then, we obtain a first set equations by imposing that the difference of two dust-weighted bolometer (or bolometer pair) maps,

$$\frac{M_b^{\nu}}{F_{\text{dust},b}^{\text{fit}} P_d} - \frac{M_b^{\nu}}{F_{\text{dust},b}^{\text{fit}} P_d},$$

must be correlated with the CO template (weighted by the dust map). A second set of equations is obtained by searching for the factor $\gamma$ that minimizes the correlation of the difference

$$\frac{M_b^{\nu}}{F_{\text{dust},b}^{\text{fit}} P_d} - \gamma \left( \frac{M_b^{\nu}}{F_{\text{dust},b}^{\text{fit}} P_d} \right)$$

with the CO dust-weighted template, $P_{\text{CO}}/P_d$. Uncertainties in the final CO conversion coefficients are obtained from the dispersion of the coefficients found for different sky regions. For the CO(1 $\rightarrow$ 0) line we use sky regions for which the Dame et al. (2001) map is above 2 K km s$^{-1}$. For the $J = 2 \rightarrow 1$ and $J = 3 \rightarrow 2$ lines we consider only the nine brightest CO clouds in the Dame et al. (2001) map.

The sky CO conversion coefficients\(^3\) (normalized to their mean value) obtained from this analysis are presented in the right column of Table 2 and compared to $^{12}$CO bandpass conversion coefficients in Fig. 2. The discrepancy between the relative values of the bandpass and sky-calibrated CO conversion can be explained from the quoted uncertainties. A more detailed comparison of sky-calibrated and bandpass computed CO conversion coefficients, and a description of the systematic uncertainties is given in the Planck Collaboration IX (2014) companion paper. However, it is important to notice that they are not expected to be equal as the sky-calibrated CO conversion coefficients account also for the contribution of other spatially correlated CO isotopologues, mainly $^{13}$CO and other molecular lines. This is extensively discussed in Sect. 6.2.2.

Finally, note that for the $J = 2 \rightarrow 1$ and $J = 3 \rightarrow 2$ lines the maps obtained from the sky-calibrated CO conversion coefficients are calibrated in the Dame et al. CO(1 $\rightarrow$ 0) line units and need to be re-calibrated to their actual frequencies; this is the purpose of the next section.

### 3.4. Unit convention

In the following the Planck CO maps are extracted using the sky-calibrated CO conversion coefficients. As discussed above these coefficients convert from the units of the Dame et al. (2001) survey, used as a CO template, to the original $K_{\text{CMB}}$ units of the Planck HFI maps. To be useful for scientific purposes these maps must be converted into the emission of the transition line. This is done by recalibrating the Planck CO maps so that they are in units of the expected $^{12}$CO contribution at the transition frequency:

$$M_{\text{CO}}^{\text{final}} = M_{\text{sky,CO}}^{\text{sky}} \times \frac{P_{\text{sky}}}{P_{\text{BP}}}$$

Here $M_{\text{sky,CO}}^{\text{sky}}$ is the CO map of any transition calibrated on the Dame et al. (2001) data, using the sky-calibrated CO conversion coefficients. The quantities $\langle P_{\text{BP}} \rangle$ and $\langle P_{\text{sky}} \rangle$ are the average across detectors of the bandpass-determined and sky-calibrated $^{12}$CO conversion coefficients.

### 4. Extracting CO from Planck data

To extract the CO emission from the Planck maps, three main approaches have been considered: i) a single channel analysis (Sect. 4.2.1); ii) a multi-channel approach (Sect. 4.2.2); and finally iii) a multi-line approach (Sect. 4.2.3) using fixed CO line ratios. While the two first methods allow us to reconstruct specific CO transition lines, the third one does not discriminate between CO transitions, but formally yields the best signal-to-noise ratio. Before detailing the specifics of these approaches, we present in Sect. 4.1 the various component separation methods that have been used and adapted to the specifics of CO observations with the Planck satellite.

#### 4.1. Component separation methods

Component separation algorithms as presented in Planck Collaboration XII (2014) are specifically tailored for CMB extraction and its statistical analysis. Thus, for this paper we have adapted and tested several of these algorithms for CO extraction from which we have selected three. Here we give a brief overview of them and of their main characteristics, while a more detailed description can be found in the references given below.

##### 4.1.1. MILCA

The MILCA (Modified Internal Linear Combination Algorithm) method (Hurier 2012) was specifically developed within the Planck collaboration for the reconstruction of thermal Sunyaev-Zeldovich effect and CO contributions on the Planck maps. MILCA is an extension of the standard Internal Linear Combination (ILC) algorithm originally developed for CMB extraction (Bennett et al. 2003; Eriksen et al. 2004). ILC algorithms assume that the desired physical component can be obtained as a weighted linear combination of the input maps.

---

\(^3\) Compatible results within statistical errors are obtained when performing a similar, but independent, analysis using the Commander component separation method (Eriksen et al. 2008) described in Sect. 4.1.3. These results show that these CO conversion coefficients are robust against some possible systematic effects on the method.
has been extensively tested using the FFP6 Commander-Ruler algorithm, as it is used to extract simultaneously several sources of sky emission and in particular the CO emission. The CO map obtained in this way is presented in this paper. The main advantages of this solution are to give access to the first three transitions of CO at the native resolution of the Planck maps and to avoid contamination from other channels. However, this type of CO extraction results in a lower signal-to-noise ratio due to the use of individual bolometer (bolometer pair) maps.

CO extraction strategies

4.2.1. Single-channel approach – Type 1 maps

In the single-channel approach we exploit differences in the spectral transmission of a given CO line among the bolometers (bolometer pairs) of the same frequency channel. As discussed in Sect. 3 the spectral bandpasses of the bolometers within a frequency channel are different. This means that the fraction of CO emission with respect to the total emission will be also different. We can construct maps of the sky for each of the bolometers, b, in a given frequency channel, ν. These maps, \(M_b^\nu\), can be considered as a linear combination of different sky emission sources including CMB, Galactic thermal dust and CO emissions at frequencies between 100 and 353 GHz:

\[
M_b^\nu = I_C^CMB + F_dust(\nu) \times I_dust^\nu + F_CO(\nu) \times I_CO^\nu + \text{noise terms.}
\]  

(5)

As these bolometer maps are calibrated in CMB temperature units and assuming that the dust emission does not vary across different frequencies and the Planck channel specifications, namely instrumental noise and bandpass. A comprehensive description of the method is given in Planck Collaboration XII (2014). Validation on simulations are presented in Appendix B.

Note that Ruler and MILCA have both been tested in the single- and multi-channel configurations described in Sect. 4.2 and were found to produce compatible results. This brings confidence in the robustness of these independent algorithms.

4.1.3. Commander-Ruler

The Commander-Ruler component separation pipeline consists of two steps: i) the Planck frequency channel maps are brought to a common resolution and the likelihoods of the non linear degrees of freedom of a chosen parametric sky-emissions model are jointly sampled, through a Gibbs sampling Monte-Carlo algorithm (Commander, Eriksen et al. 2008); ii) for each sample of the derived distribution, the linear degrees of freedom, namely the amplitude maps of the components, are computed at the full Planck resolution via a generalized least squares solution (Ruler, described above). The first and second moments of the posterior distribution of a parameter define its mean value and uncertainty, which accounts for both the instrumental and unwanted components modelling error.

A comprehensive description of the Commander-Ruler method is given in Planck Collaboration XII (2014) where it is used to extract simultaneously several sources of sky emission and in particular the CO emission. The CO map obtained in this way is presented in this paper. Commander-Ruler has been extensively tested using the FFP6 simulations (see Planck Collaboration 2013) as part of Planck component separation, a thorough description of which is provided in Planck Collaboration XII (2014).

N(bolo. maps) (bolometer or channel maps). They search for the weights of such a linear combination of maps that minimise the variance of the solution with given constraints, which are designed to project out the desired physical component. MILCA provides a flexible way of selecting wanted and unwanted spectral components (Hurier et al. 2013; Hurier 2012) and corrects for the noise bias in standard ILC algorithms. Furthermore, the weights of the internal linear combination can be computed both in real and harmonic space to improve the component separation efficiency. MILCA was tested against CO-oriented simulations, showing no bias in the reconstruction when the CO conversion coefficients are perfectly known (see Appendix B).
\( \beta = 1.6 \) and \( B_r(T) \) is the Planck function. The choice of this dust spectrum is discussed in Sect. 6.2.1.

At 353 GHz, the CMB becomes sub-dominant compared to the dust and we require an estimate of the CO, only removing the dust. We also found that the dust spectrum model used for the \( J = 2 \rightarrow 1 \) line is not optimal at 353 GHz and thus we used the sky-calibrated dust conversion coefficients \( F^\text{sky} \) which were also fitted in the linear regression of Eq. (3) and for which we obtained better results.

4.2.2. Multi-channel approach – TYPE 2 maps

The multi-channel approach makes use of the intensity maps in several channels to isolate the CO contribution from other astrophysical sources of emission. As discussed above, the Planck intensity map for a given frequency channel, \( v \), is the linear combination of different sources of emission including mainly CMB, Galactic thermal dust, free-free and CO:

\[
M_v = I^{\text{CMB}} + F_{\text{dust}}(v) \times I^{\text{dust}} + F_{\text{ff}}(v) \times I^{\text{ff}} + F_{\text{CO}}(v) \times I^{\text{CO}} + \text{noise terms,}
\]

where \( I^{\text{CO}} \) corresponds to the emission of the \( J = 1 \rightarrow 0 \), \( J = 2 \rightarrow 1 \) or \( J = 3 \rightarrow 2 \) lines. The relative contribution of these emissions changes between channels. For example the 100 GHz channel shows CO emission while this is not the case for the 70 and the 143 GHz channels and it can be considered negligible at 353 GHz. Thus, combining the maps of these four channels we should be able to reconstruct the CO emission using component separation techniques as above.

The Ruler method was selected to be used in this configuration, to extract the \( J = 1 \rightarrow 0 \) and \( J = 2 \rightarrow 1 \) lines. In order to construct the CO(1 \( \rightarrow \) 0) line, we use LFI 70 GHz, HFI-100, 143 and 353 GHz channels, while CO(2 \( \rightarrow \) 1) is obtained using LFI 70 GHz, 143, 217 and 353 GHz channels. All maps are smoothed to 15\(^\circ\). To solve for the two CO transitions, we assume that the CO contribution to the 353 GHz channel is negligible\(^4\). The CO(1 \( \rightarrow \) 0) and CO(2 \( \rightarrow \) 1) maps obtained using the multi-channel method constitute the Planck TYPE 2 CO product.

For both lines, the requirement is to extract CO while at the same time fitting for CMB, dust and free-free emission. By construction, the CMB spectrum is flat across channels. For the dust, the same grey-body spectrum as for the single-channel \( J = 2 \rightarrow 1 \) line is assumed. Free-free emission is modelled as a power-law spectrum proportional to \( \nu^{-2.15} \). The dust and free-free transmission coefficients are obtained by integrating their spectra over Planck’s bandpasses.

4.2.3. Multi-line approach – TYPE 3 map

While the multi-channel approach provides single line maps at relatively high signal-to-noise ratio, it is possible to use a multi-line approach to further increase the S/N ratio, potentially allowing the discovery of new faint molecular clouds at high Galactic latitudes. For this, we need to assume that the line ratios, CO(2 \( \rightarrow \) 1)/CO(1 \( \rightarrow \) 0) and CO(3 \( \rightarrow \) 2)/CO(1 \( \rightarrow \) 0), are constant across the sky. This is equivalent to considering the CO emission to be the same at 100, 217 and 353 GHz up to a multiplicative factor that is assumed to be known. Under these assumptions Eq. (6) reads

\[
M_v = I^{\text{CMB}} + F_{\text{dust}}(v) \times I^{\text{dust}} + F_{\text{ff}}(v) \times I^{\text{ff}} + F_{\text{CO}}(v) \times I^{\text{CO}} + \text{noise terms.}
\]

This approach is used as part of the Commander-Ruler pipeline employed for CMB component separation (Planck Collaboration XII 2014).

The TYPE 3 CO map results from a seven-band run of this pipeline, including 30 to 353 GHz channel maps, with the sky modelled as a superposition of CMB, CO, dust – treated as a modified blackbody – and a power law to describe the low-frequency Galactic emission. The dust optical depth and the dust temperature, as well as the low-frequency component spectral index are fitted at every pixel. Since the total number of parameters would exceed the number of frequencies considered, the three CO lines are assumed to be perfectly correlated. A single CO map is solved for, the so-called TYPE 3 map, using the average CO bandpass transmission (see Sect. 3.2) in each channel, whereas the CO line ratios are given by the posterior average of the distribution obtained from a dedicated Commander run on small bright CO regions (Taurus, Orion, Polaris, etc.). The line ratios found for CO(2 \( \rightarrow \) 1)/CO(1 \( \rightarrow \) 0) and CO(3 \( \rightarrow \) 2)/CO(1 \( \rightarrow \) 0) are 0.595 and 0.297, respectively. Notice that there are significant spatial variations of these ratios as discussed in Sect. 6.2.2. For further analysis we have selected bright CO regions with large ratios.

5. Planck CO maps

The Planck CO delivery consists of three types of products, corresponding to the three extraction methods described above:

- TYPE 1 maps are extracted using the single-channel approach described in Sect. 4.2.1 and come at the native resolution of the corresponding Planck-HFI channel;
- TYPE 2 maps come from the multi-channel method given in Sect. 4.2.2 and have a resolution of 15\(^\circ\);
- TYPE 3 map comes from the multi-line approach described in Sect. 4.2.3, assuming fixed CO line ratios in order to obtain the highest possible signal-to-noise ratio, and is delivery at a resolution of ~5/5.

The main characteristics of all Planck CO maps are shown in Table 3 while details of the Planck CO product is given in Appendix A. The TYPE 1, TYPE 2 and TYPE 3 terminology will be used throughout the paper. All maps discussed below are in units of K km s\(^{-1}\) at the transition line they represent.

5.1. The CO J = 1 \( \rightarrow \) 0 line at 115 GHz

The TYPE 1 (top), TYPE 2 (middle) and TYPE 3 (bottom) Planck CO(1 \( \rightarrow \) 0) maps are given in the left column of Fig. 3. The right column corresponds to their statistical error and will be discussed further in Sect. 6.

The resolution of the TYPE 1 product is 9/65, i.e., the native resolution of the Planck-HFI 100 GHz channel. The TYPE 2 product has a 15\(^\circ\) beam due to the additional smoothing required to combine several Planck channels: in particular the use of Planck-LFI 70 GHz channel is essential to remove the free-free emission (see Sect. 6.2). Finally, the TYPE 3 has varying resolution across the sky, resulting from the Ruler solution, and a beam profile is computed from FFP6 simulations. A good

\(^4\) While this assumption eases the CO extraction, it also leads to an overall systematic calibration error that can be corrected for afterwards (see Sect. 6.2).
Gaussian approximation can be achieved with a FWHM of 5.5. A simple eye inspection finds a good overall agreement between the maps; an in-depth comparison is conducted in Sect. 7.

5.2. The CO J = 2 → 1 line at 230 GHz

The CO(2 → 1) line can only be extracted using the single-channel or the multi-channel approach. Therefore the 230 GHz Planck CO product consists of Type 1 (5′ resolution) and Type 2 (15′ resolution) maps only, which are displayed in the left column of Fig. 4. The dust emission increases with frequency and becomes more of an issue for the J = 2 → 1 line extraction. This will be discussed at length in Sect. 6.2, but this issue is already clearly visible when comparing the two products: the Type 2 CO presents diffuse dust emission throughout the Galactic plane that is not present in the Type 1 map.

5.3. The CO J = 3 → 2 line at 345 GHz

As mentioned previously, the single-channel approach is the only way to extract this higher J CO line and the corresponding Type 1 CO map is shown in Fig. 5. This map has a resolution of 4′/82.

Fig. 3. Full-sky CO J = 1 → 0 maps (left) and their respective statistical error maps (right) in K km s⁻¹ units for the three types of Planck CO products. For display purposes only, the Type 1 and Type 3 maps are smoothed to 15′ to ease the comparison to the Type 2 maps. The error maps correspond to the non-smoothed product. The maps are in Galactic coordinates and follow the HEALPix pixelization scheme for Nside = 2048.
We compare the reconstructed CO intensity for the different rotational transition lines to the total emission in the Planck original channel maps. For the $J = 1 \rightarrow 0$ line the CO intensity in well-known molecular clouds and in the Galactic plane corresponds on average to about 50% of the total emission in the 100 GHz channel map. The $J = 2 \rightarrow 1$ line is about 15% of the 217 GHz channel map and the $J = 3 \rightarrow 2$ is about 1% of the 353 GHz map. At high Galactic latitudes the CO contribution is negligible on average for the three lines.

6. Uncertainties and contaminants

6.1. Statistical errors

Statistical uncertainties in the CO maps may be obtained using so-called half-ring half differences\(^5\) (Planck HFI Core Team 2011b). For the Type 1 product, standard deviation ($\sigma$)-maps

\(^5\) First and last ring sets are independent data sets built using the first and second half of the stable pointing periods (see Sect. 2).
are generated at the level of individual bolometer maps, starting from the half-ring half difference noise map whitened using the number of hits in each pixel. A given bolometer σ-map, \( \sigma_b \), is then obtained by dividing the standard deviation of the noise map by the square root of the number of hits in each pixel, namely

\[
\sigma_b = \frac{1}{\sqrt{N_b}} \text{stddev} \left[ \frac{M_{b2}^T - M_{b1}^T}{2} \sqrt{N_b} \right],
\]

where \( N_b \) is the hit number map and \( M_{b1}^T \) and \( M_{b2}^T \) are the first and last half-ring bolometer maps respectively. This standard deviation of each bolometer map \( \sigma_b \) is then propagated quadratically to the CO map level using the weights found by MILCA for the linear combination.

This cannot be achieved in such a straightforward fashion for the TYPE 2 maps smoothed to 15', resulting in correlated noise. Given the size of the maps, a fully dense matrix description of the noise is not feasible. However, a set of 1000 realistic noise simulations has been processed through the pipeline (first smoothed and then linearly combined), and used to compute a σ-map, which is a good pixel noise approximation. The TYPE 3 standard deviation map is obtained in a similar fashion.

The σ-maps of all Planck CO maps are plotted in the right columns of Figs. 3–5. For the TYPE 1 and TYPE 3 CO(1 → 0) maps, the σ-maps correspond to the maps at their native resolutions, while the CO maps have been smoothed to 15' for display purpose. These standard deviation maps have all been validated by checking that their mean at high latitude was in agreement with standard deviation measured directly in the CO map at these locations (where no signal is expected; see lower panel of Fig. 17).

Using a common resolution of 15' to compare the high-latitude noise level in the maps, we find the standard deviation of the CO(1 → 0) maps to be typically 1.77 K km s\(^{-1}\) for the TYPE 1 map, 0.45 K km s\(^{-1}\) for the TYPE 2 map and 0.16 K km s\(^{-1}\) for the TYPE 3 map. These uncertainties can be compared with typical uncertainties on ground-based surveys for CO(1 → 0) for example 0.6 K km s\(^{-1}\) for the Dame et al. (2001) and NANTEN (Mizuno & Fukui 2004) surveys. At the same resolution, the TYPE 1 and TYPE 2 CO(2 → 1) maps have standard deviations of 0.74 K km s\(^{-1}\) and 0.12 K km s\(^{-1}\), respectively, while it is 0.73 K km s\(^{-1}\) TYPE 1 CO(3 → 2) map.

### 6.2. Contaminants

All Planck CO products suffer from systematic effects and contamination from other emission that needs to be characterized; point sources or emission from other CO lines affect all Planck CO products while dust, free-free emission and the Sunyaev Zeldovich effect (SZ) are important for TYPE 2 and TYPE 3 maps only (the TYPE 1 product is the most immune to contamination as it relies on single-channel information). Some of these contaminants (e.g., CMB, dust, free-free), need to be dealt with at the stage of component separation. Others, like point sources and the thermal SZ effect in clusters of galaxies, may simply be masked afterwards. We discuss each of these contaminants in detail below apart from CMB emission for which the electromagnetic spectrum is well-known and can be explicitly nullified within calibration errors in the Planck frequency maps, as discussed in Sect. 4.1.

#### 6.2.1. Dust

Dust emission is the main contaminant as far as CO is concerned and is often strong in the same regions, e.g., star forming regions. The multi-channel approach (i.e., TYPE 2 products) is particularly sensitive to the choice of the dust spectrum. One assumption we make in these maps is that the dust spectrum is constant over the sky and described by a grey-body with \( T_{dust} = 17 \) K and \( \beta_{dust} = 1.6 \). This assumption is not correct since both the spectral index and temperature of the dust are known to vary across the sky (see, for example, Planck Collaboration XIX 2011; Fauvet et al. 2013). These values are, however, a good representation of the dust found in CO-rich regions as can be seen on the \( \beta_{dust} \) and \( T_{dust} \) maps of Planck Collaboration XI (2014); Planck Collaboration XII (2014).
As far as the dust transmission in HFI is concerned, $\beta_{dust}$ and $\tau_{dust}$ are degenerate quantities. Testing different values of the $\beta_{dust}$ index, we find this dust model to be the best compromise for the multi-channel CO extraction. At $\tau_{dust} = 17$ K, choosing $\beta_{dust} = 1.5$ results in too much dust removal and a negative residual in the Galactic plane. Conversely, $\beta_{dust} = 1.7$ generates much larger remaining dust emission. In the outer regions of the TYPE 2 maps ($l > 90^\circ$ and $l < 270^\circ$), changing $\beta_{dust}$ by $\pm 0.1$ yields an increase/decrease of less than about 1 K km s$^{-1}$ at 115 GHz and less than about 2 K km s$^{-1}$ at 230 GHz. Still, these are larger than statistical errors. The inner regions of the Galactic plane are far more sensitive to the change of the dust spectrum, with a shift of about 10 K km s$^{-1}$ at 115 GHz and 15 K km s$^{-1}$ at 230 GHz, but the signal is much larger.

Given our chosen dust model, Fig. 6 shows the correlation between the types of $J = 1 \rightarrow 0$ CO maps discussed above and Planck’s 545 GHz map used here as dust template. All maps were smoothed to $30^\prime$. The comparison has been done in three molecular clouds hosting different environments: i) Orion, a very active massive star forming region; ii) Taurus, that hosts low-mass star formation (Kenyon et al. 2008); and iii) Polaris, a high-Galactic latitude translucent cloud with little to no star formation and presenting both atomic and molecular gas (Miville-Deschênes et al. 2010). Figure 7 presents smoothed images of the three regions for the TYPE 1 and TYPE 2 Planck CO maps and for Planck’s 545 GHz channel. Snapshots of the Dame et al. (2001) $J = 1 \rightarrow 0$ data are also shown in Fig. 7 but will be discussed in Sect. 8.1.

Dust emission is quite intense in both Orion and Taurus (Fig. 7, right column) and, as can be seen in Fig. 6, some correlation is not unexpectedly found between the Planck CO maps and the dust template in these locations. This is particularly true in Orion where the images show very similar patterns of CO and dust. In the Polaris region the correlation loosens significantly; dust is far less intense and shows a different distribution than CO. For the weakest dust emission, probably in atomic gas, there is no CO signal. These correlation plots against dust should be compared with those performed against ground-based CO measurements, where the correlation is this time much tighter (this is discussed in Sect. 8.1; see Fig. 10). Looking at several other molecular clouds (e.g., Ophiuchus, Chameleon), we find that whatever the method, the correlation with CO is always much tighter than the one with dust, making us confident that dust is not a major issue for CO-rich regions.

Nonetheless, TYPE 2 and TYPE 3 maps do suffer some level of dust contamination. This can be seen by eye in the CO($1 \rightarrow 0$) images of the Taurus regions in Fig. 7 (top) where the TYPE 2 map shows more flux than the TYPE 1 CO at the locations where the dust is the brightest. However, contamination is the most important in the Galactic plane of the CO($2 \rightarrow 1$) TYPE 2 map. This is particularly visible in Fig. 4.

### 6.2.2. Other CO lines

For all of the Planck reconstructed CO maps we expect contamination from other CO isotopologue transition lines. Lines from the $^{13}$CO isotopologue are the main contaminants in the TYPE 1 maps, while $^{12}$CO and the $^{12}$CO($3 \rightarrow 2$) both contribute to the TYPE 2 maps. The contribution of each contaminant line can be estimated to first order as follows:

\[ \text{CO}^{\text{X}} = \frac{1}{13} \text{CO} \sum_i w_i F_{i2}^{\text{type2}} + \frac{1}{353} \text{CO} \sum_i w_i F_{i3}^{\text{type2}}, \]

where $X$ represents the $J = 1 \rightarrow 0$, $J = 2 \rightarrow 1$ or $J = 3 \rightarrow 2$ transition, $w_i$ are the weights of the linear combination and $F_{i2}^{\text{type2}}$ is the $^{12}$CO emission in bolometer $i$. Using the weights of the TYPE 1 linear combination and using the bandpass coefficients for $^{13}$CO, we find the quantity $\sum_i w_i F_{i3}^{\text{type2}}$ to be equal to 0.53 at 115 GHz, 0.01 at 230 GHz and 0.36 at 353 GHz. Assuming a $^{13}$CO to $^{12}$CO ratio of 0.2, this translates in CO$_{\text{type2}} = 1.1 \times 10^{-2}$ and CO$_{\text{type2}} = 1.07 \times 10^{12}$ CO$^{-2}$, i.e., an overestimation of about 10% of the TYPE 1 $J = 1 \rightarrow 0$ and $J = 3 \rightarrow 2$ maps. The effect on the $J = 2 \rightarrow 1$ transition is negligible.

### TYPE 2: forgetting about other contaminants, the CO content of the TYPE 1 Planck map can be written as

\[ \text{CO}^{\text{X}} = \frac{1}{13} \text{CO} \sum_i w_i F_{i2}^{\text{type2}} + \frac{1}{353} \text{CO} \sum_i w_i F_{i3}^{\text{type2}}, \]

\[ = 10^{-2} \text{CO}\left(\frac{1 + w_{353}(F_{i2})_{353}}{w_{353}(F_{i2})_{353}}\right)\text{CO}^{\text{type2}} + \frac{1}{13} \text{CO}^{\text{type2}}, \]

where $(F_{i2})_{353}$ are the average (among bolometers) conversion coefficients of $^{12}$CO and $^{13}$CO at 100 or 217 GHz, depending on the transition under scrutiny and $(F_{i3})_{353}$ is that of $^{13}$CO in the 353 GHz channel. In the following, we assume the line ratios to be $^{13}$CO($3 \rightarrow 2$)/$^{12}$CO($1 \rightarrow 0$) = 0.2 and $^{13}$CO($3 \rightarrow 2$)/$^{12}$CO($2 \rightarrow 1$) = 0.4 as obtained from the median of the line ratio distributions computed from the TYPE 1 maps, (see Planck Collaboration PIP, in prep.). The widths of the distributions are large and thus we consider uncertainties of $\pm 0.1$ in the two ratios. Notice that within these uncertainties the values considered here are consistent with those derived from the Ruler analysis in Sect. 4.2.3. Using these values we find $\text{CO}^{\text{type2}} = 1.02 \times 10^{12}$ CO$^{-1}$ and $\text{CO}^{\text{type2}} = 0.75 \times 10^{12}$ CO$^{-2}$.

From this, we see that contamination from the $J = 3 \rightarrow 2$ line can be neglected in the $J = 1 \rightarrow 0$ TYPE 2 map, but reduces by $\sim 25\%$ the $^{12}$CO signal in the $J = 2 \rightarrow 1$ map. For this reason, we decided to correct the TYPE 2 map from this effect by dividing the output TYPE 2 ($J = 2 \rightarrow 1$) map by 0.75. With this correction, the overall calibration of the TYPE 1 and TYPE 2 ($J = 2 \rightarrow 1$) maps are in agreement (see Sect. 7).

The second term of the contamination due to $^{13}$CO can now be estimated. Using the bandpass estimate of the coefficients, $(F_{13}/F_{12})_{353}$ is equal to 1.14 at 115 GHz and 0.82 at 230 GHz, which translate into CO$_{\text{type2}} = 1.2 \times 10^{12}$ CO$^{-2}$ and $^{13}$CO$_{\text{type2}} = 1.2 \times 10^{12}$ CO$^{-2}$ when assuming a ratio of 0.2 between $^{12}$CO and $^{13}$CO and the 0.75 correction factor for the $J = 2 \rightarrow 1$ line.

The values above are given as a rough estimate of the $^{13}$CO contamination. The latter depends on the isotopic ratio and relative optical depth, and will, in practice, vary across the sky.
Fig. 7. Images (12\(^{\prime}\)5 × 12\(^{\prime}\)5) of the Taurus (left column – centered on \((l,b) = (173^{\circ},-15^{\circ})\)), Orion (middle column – centered on \((l,b) = (210^{\circ},-14^{\circ})\)) and Polaris (right column – centered on \((l,b) = (124^{\circ},26^{\circ})\)) regions considered throughout the paper. The first row corresponds to the Dame et al. (2001) survey. The two middle rows show the Type 1 and Type 2 \(J = 1 \rightarrow 0\) Planck CO products. The Planck-HFI 545 GHz channel map, used as a dust template, is shown in the last row. All maps are smoothed to 30\(^{\prime}\).

6.2.3. Masking SZ clusters and point sources

Planck CO maps are also contaminated by other localized non-CMB signals that have not been included in the component separation. This is the case of radio point sources, which are present in all three types of maps. Also present in the maps is the Sunyaev-Zeldovich (SZ) effect, a secondary anisotropy of the CMB coming from the interaction of CMB photons with the hot electron population of galaxy clusters. The Planck mission has shown the potential of galaxy cluster detection via the SZ effect with the publication of a catalogue of a few thousands clusters (Planck Collaboration XXIX 2014). As far as CO extraction is concerned, SZ is yet another contaminant foreground in the Type 2 and Type 3 maps, as these rely on multi-channel information. On the other hand, Type 1 maps are not affected.

For this first release of the Planck CO maps, a point source mask is provided with the Type 1 and a point source + SZ mask for the Type 2 and Type 3 maps. The point source mask used here was constructed from the Planck-HFI official 100 GHz point source mask by unmasking any pixels located within \(|b| < 1.5^{\circ}\). This manipulation was necessary given that many point sources in the mask are molecular cold cores located in the Galactic disk, so that using the original mask hides most of the Galactic CO. For the SZ mask we start from a simulated Compton parameter map of the Planck cluster sample (Planck Collaboration XXIX 2014; Planck Collaboration XII 2014) where a universal generalized pressure profile (Arnaud et al. 2010) was assumed. The mask is then generated by imposing a threshold of 4 × 10\(^{-6}\) in Compton parameter units to this map.

6.3. Absolute calibration uncertainties

Three main contributors to the absolute calibration uncertainties of the Planck CO maps have been identified: i) the Planck-HFI calibration uncertainties of the temperature maps; ii) the uncertainty on the CO bandpass conversion coefficients; and iii) the uncertainty on the \(^{13}\text{CO}\) contribution. We do not include the effect of dust in this absolute calibration given that, contrary to \(^{12}\text{CO}\), dust is not always spatially correlated to CO and is therefore considered as a systematic effect (see Sect. 6.2.1).
As described in Planck Collaboration VIII (2014), the absolute calibration of the Planck maps is about 0.55% from 100 GHz to 217 GHz, 1.25% at 353 GHz, and 10% at 545 and 857 GHz. Uncertainties on the averaged bandpass CO conversion coefficients are at the 5% level at 100 GHz and 1% at 217 and 353 GHz (Planck Collaboration IX 2014). We described how $^{13}$CO affected the Planck CO maps in Sect. 6.2.2; using the results obtained with $^{13}$CO/$^{12}$CO = 0.2 (Solomon et al. 1979), and assuming a conservative uncertainty of ±0.1 on this ratio, we can estimate the $^{13}$CO contribution to the absolute uncertainty in each CO map.

Final calibration uncertainties are summarized in Table 4. A conservative estimate of the total absolute calibration uncertainties of each map is given in the last column of the table. For most maps, the calibration uncertainties are of the order of 10% and are dominated by the $^{13}$CO contribution. Notice that for TYPE 1 CO(2 → 1) and CO(3 → 2) the uncertainties are significantly smaller as they are less contaminated by $^{13}$CO.

7. Internal validation of the CO maps

Before validating these maps on external data, it is possible to perform some internal checks by comparing the CO maps of different types. As mentioned previously, the TYPE 1 and TYPE 2 CO products can differ in the Galactic plane because of the higher level of contamination affecting the TYPE 2 products. However, at high Galactic latitudes, where no significant free-free or dust emission is expected, the products may be compared in order to assess the overall inter-calibration of the TYPE 1, 2 and 3 CO maps. To perform this comparison, the maps are first smoothed to a common resolution of 30′ and degraded to $N_{\text{side}} = 128$ to avoid noise correlation between samples. After masking point sources, correlation plots are produced for all remaining pixels located at Galactic latitudes $|b| \geq 25^\circ$.

Figure 8 compares both TYPE 1–TYPE 2 and TYPE 1–TYPE 3 maps. At high latitudes, CO emission is very sparse so that most pixels have very low emission. Therefore, below an empirical threshold, shown as the dashed line in each figure, the number of points is such that a contour representation of binning suffices. Above the dashed line, individual pixels are plotted directly and used to compute the best fit. The orange line gives the best-fit values and is compatible within errors with perfect correlation ($y = x$). This indicates that the different types of product share the same overall calibration, both for the $J = 1 \rightarrow 0$ maps (Fig. 8, left and middle panel) and $J = 2 \rightarrow 1$ maps (Fig. 8, right panel).

The different types of product may also be compared in specific molecular clouds, as shown in the top and bottom panels of Fig. 9 for the $J = 1 \rightarrow 0$ (top) and $J = 2 \rightarrow 1$ (bottom) lines, respectively. As for the comparison to dust, the Taurus (left), Orion (middle) and Polaris (right) molecular clouds have been chosen because of the three very different molecular environments they host. Figure 9 shows tight correlations between the TYPE 1 and TYPE 2 CO(1 → 0) products in these three molecular clouds. The best fits are computed for all points in the range [2–15] K km s$^{-1}$, where the bulk of the emission lies. The fit uncertainties are dominated by the errors bars (not shown in the figure) of the TYPE 1 points. The TYPE 2 CO(1 → 0) map shows more flux than the TYPE 1 with best-fit slopes of about 1.1 for Taurus, Orion and Polaris. Such behavior is nonetheless expected, given that the TYPE 2 CO(1 → 0) map suffers from more $^{13}$CO and dust contamination than the TYPE 1 CO(1 → 0)
map as described in Sects. 6.2.2 and 6.2.1. Similar trends are observed for the CO(2 → 1) maps (bottom panel), but here we also give as dashed lines the best-fits that would have been obtained for a change of ±0.1 in the \(^{13}\)CO(3 → 2)/\(^{12}\)CO(2 → 1) ratio assumed to correct the TYPE 2 map from the \(^{13}\)CO(3 → 2) contamination (see Sect. 6.2.2). Given the absolute calibration and statistical uncertainties quoted above for each of the maps, the residuals between the TYPE 1 and TYPE 2 maps are consistent within the errors.

8. Comparison with external data

In this section, we validate the Planck CO products described in Sect. 5 using existing ground-based CO data for the first three transition lines.

8.1. Comparison with the Dame et al. (2001) CO \(J = 1 \rightarrow 0\) survey

The publicly available data of Dame et al. (2001) represent the most complete survey of Galactic \(^{12}\)CO \(J = 1 \rightarrow 0\) emission to date. The original data consist of a composite map constructed from a set of 37 independent surveys taken by the 1.2 m Millimetre-Wave Telescope at the CfA.\(^7\) In order to compare the Planck CO maps to the Dame et al. (2001) data, we use the velocity-integrated HEALPix rendition of the survey which is available on the Lambda website.\(^8\)

8.1.1. Molecular clouds

We focus again on the three molecular clouds, Taurus, Orion and, Polaris. Images of the Dame et al. (2001) and Planck data in these fields are shown in Fig. 7. The maps were smoothed to a common resolution of 30’ and degraded to \(N_{\text{side}} = 128\) (to avoid noise correlation between samples) before plotting the correlations shown in Fig. 10. In each panel of this figure, the three types of Planck CO \((1 \rightarrow 0)\) maps (shown in different colours) are correlated with the Dame et al. (2001) data. The slopes of the best-fit linear regressions for the three products are given in the legend of each panel (with a 1-\(\sigma\) statistical error smaller than 1%). The spread in the data points is reminiscent of the level of noise in the maps, showing once again that the TYPE 1 map is the noisiest while the TYPE 3 map has the best signal-to-noise ratio.

The TYPE 1 CO is in good agreement with the Dame et al. (2001) data, with a slope of about 1.05 in both Taurus and Orion. The excess with respect to the one-to-one correlation is at the level expected from \(^{13}\)CO contamination (see Sect. 6.2.2). For Polaris the slope is about 1.1, but in such faint regions, the level of noise of the TYPE 1 map makes the comparison more difficult. For all clouds, the TYPE 2 CO show roughly 20% excess compared to the Dame et al. (2001) data due to a combination of both dust and \(^{13}\)CO contamination. It performs particularly poorly in Orion where the dust is significantly correlated with CO emission. Finally, the TYPE 3 CO does as well as the TYPE 1 product in Taurus, but also suffers from some contamination in Orion with a correlation of 1.16. This test was conducted in other molecular regions (not shown here) and similar trends were found. The level of the residuals is always compatible with the calibration uncertainty of the maps.

From these, we conclude that the TYPE 1 map is the most robust \(J = 1 \rightarrow 0\) map in terms of CO extraction, but its low S/N ratio makes it unsuitable for the study of faint CO regions. The TYPE 2 and TYPE 3 maps both suffer from some level of dust contamination but allow us to probe fainter regions and to perform discovery studies.

8.1.2. Velocity effect in the TYPE \(J = 1 \rightarrow 0\) map

After checking the behaviour of our maps in these specific locations, we focus here on the Galactic plane as a whole. Still working at 30’, the Planck map has been degraded to \(N_{\text{side}} = 512\) in order to match the HEALPix resolution of the Dame et al. (2001). The Planck map has been recalibrated to the Dame et al. data by performing a linear regression on all pixels \((\text{CO}_{\text{type}} \approx 1.16 \times ^{12}\text{CO}_{\text{Dame}})\), after which operation the difference was taken. Figure 11 shows the residual between the TYPE 1 CO\((1 \rightarrow 0)\) map and Dame et al. (2001) Galactic plane composite survey. We observe a clear modulation pattern in the Galactic disk, producing a positive residual at longitude \(l < 90^\circ\) and a negative residuals at \(l > 270^\circ\). This residual can reach 5% of the total intensity of CO and it is interpreted as the signature of the rotation of the Galactic disk. Because the CO line frequency is shifted due to the Doppler effect, the emission along different line-of-sight with different velocities produces a different CO response in a given bolometer. The effect is then averaged over all bolometers in the final reconstructed CO map. Using the mean velocity of CO emission in the Dame et al. (2001) survey, we can fit the residuals as a linear function of the velocity. We find that this effect at the \(J = 1 \rightarrow 0\) transition is well represented by \(\text{CO}_{\text{type}} = \text{CO}_{\text{Dame}} - \frac{0.1}{v} \times 800 \text{ km s}^{-1} \times \text{CO}_{\text{Dame}}\), where \(v\) is the radial velocity of the gas. This formula was also found consistent with the difference observed between survey maps (for which the Planck satellite velocity is modulated by the satellite revolution around the Sun) and may be used to correct the Planck map for this velocity effect. Note that this effect is not seen when performing the residuals in the same way for the TYPE 2 and TYPE 3 products as it is i) somewhat averaged out by the use of channel maps instead of bolometer maps; and ii) hidden by the higher Galactic plane contamination of these maps.

8.2. Comparison with NANTEN II \(^{12}\)CO and \(^{13}\)CO \(J = 1 \rightarrow 0\) data

Observations in both \(^{12}\)CO and \(^{13}\)CO have been carried out with the NANTEN II millimetre-submillimetre telescope at Atacama, between February 2010 and October 2012. The dish provides a half-power beam width (HPBW) of 2.6 in \(^{12}\)CO \(J = 1 \rightarrow 0\). The spectrometer is a digital Fourier spectrometer with a frequency resolution of 61 kHz and a bandwidth of 1 GHz. A Hanning window function is applied when the FFT is performed in the spectrometer, which results in a final frequency resolution of 79.3 kHz. The velocity coverage and resolution are 2600 km s\(^{-1}\) and 0.21 km s\(^{-1}\) for \(^{12}\)CO, and 2720 km s\(^{-1}\) and 0.22 km s\(^{-1}\) for \(^{13}\)CO respectively. All observations have been carried out in on-the-fly (OTF) mode, where the telescope constantly drives across the sky, with an output grid of 60’. The standard size of an OTF block is 1’ × 1’ and at least one scan of longitudinal direction and lateral direction have been done for each OTF block. Each scanning data set was combined by the basket weaving method (Emerson & Graebe 1988) to reduce scanning noise in each OTF direction. The intensity calibration was made with the chopper-wheel method.

\(^7\) The complete data set can be retrieved from http://www.cfa.harvard.edu/rtdc/CO/

\(^8\) http://lambda.gsfc.nasa.gov/
Fig. 9. Correlation between Type 1 and Type 2 CO maps at 115 GHz (left column) and 230 GHz (right column) in the Taurus (top), Orion (middle) and Polaris (bottom) molecular clouds. The best linear fits (orange solid line) have been computed between 2 and 15 K km s$^{-1}$ at 115 GHz and between 1 and 15 K km s$^{-1}$ at 230 GHz, where bulk of the data lie and avoiding the noise around zero. The best-fit slopes and uncertainties are: a) 1.12 ± 0.03; b) 1.14 ± 0.01; c) 1.10 ± 0.04; d) 1.07 ± 0.01; e) 1.07 ± 0.06; and f) 1.17 ± 0.04. The intercepts are compatible with zero within error bars. The orange dot-dashed lines in the bottom panels correspond to the recalibration uncertainty due to the contribution of the $J = 3 \rightarrow 2$ line in the Type 2 $J = 2 \rightarrow 1$ product. See text for detail.

Fig. 10. Correlation between the three types of CO products with the Dame et al. (2001) data in the Taurus (top), Orion (middle) and Polaris (bottom) molecular clouds. The best-fit slope and intercept are given in Table 5. Notice that the intercepts are in all cases below 0.7 K km s^{-1}.

Fig. 11. Residual map with respect to the Dame et al. (2001) map in K km s\(^{-1}\) for the TYPE 1 \(J = 1 \rightarrow 0\) Planck CO map. The Planck maps have been recalibrated to Dame before performing the subtraction.

8.3. Comparison with FCRAO \(^{13}\)CO \(J = 1 \rightarrow 0\) data

Along the same lines as the comparison performed with NANTEN II data, it is possible to gain further confidence in our estimation of the \(^{13}\)CO contamination using FCRAO \(^{13}\)CO(1 \(\rightarrow\) 0) data along with the \(^{12}\)CO(1 \(\rightarrow\) 0) data of Dame et al. (2001). In this analysis, we use the publicly available Boston University FCRAO Galactic Ring Survey\(^9\) (FCRAO-GRS) described in Jackson et al. (2006). It consists of a 75.4 deg\(^2\) survey of the Galactic plane, between 18\(^\circ\) \(< l < 55\(^\circ\)\) and \(|b| < 1\(^\circ\)\) at 46\(^\prime\) resolution.

We first re-project the FCRAO-GRS data into the HEALPix pixelization scheme (\(N_{\text{side}} = 2048\)) using a nearest grid-point approach and correct for the 0.48 beam efficiency given in Jackson et al. (2006). Binning over the ratio \(^{13}\)CO\(_\text{FCRAO}\)/\(^{12}\)CO\(_\text{Dame}\), we compute the average ratio \((\text{CO}_{\text{type}1})/(\text{CO}_{\text{Dame}})\) in each bin and plot the correlation in Fig. 13. Error bars are obtained assuming white noise, the amplitude of which is estimated at high Galactic latitude (\(|b| > 60^\circ\)). The standard deviation in each bin is then simply estimated using the number of pixels in the bin. We assume the noise in the Dame et al. (2001) map to be negligible.

The correlation between the two ratios is good and from the best-fit of the linear regression we see that the Planck TYPE 1 map can be written as

\[
\text{CO}_{\text{TYPE}1}^{[1-0]} = 0.53 \times \text{CO}_{\text{FCRAO}}^{[1-0]} + 1.07 \times \text{CO}_{\text{Dame}}^{[1-0]},
\]

which is agreement with the 0.53\times\(^{13}\)CO contamination estimate we made from the bandpass coefficients (see Sect. 6.2.2). This test shows, in a completely independent manner to that of the NANTEN comparison, that we have an excellent grasp on the CO content of the TYPE 1 map.

8.4. Comparison with the AMANOOGAWA-2SB CO \(J = 2 \rightarrow 1\) survey

The AMANOOGAWA-2SB survey (Handa et al. 2012; Yoda et al. 2010) carried out simultaneous Galactic plane (\(l = 10^\circ - 245^\circ\)) observations of the \(^{12}\)CO and \(^{13}\)CO(2 \(\rightarrow\) 1) transitions with the Tokyo-NRO 60-cm telescope, with a resolution and grid-spacing of 9 and 3.75 respectively. Here, we use a 35\(^\circ\) \(\times\) 8\(^\circ\)

\(^9\) The data of the BU-FCRAO-GRS may be retrieved at http://www.bu.edu/Galacticring/
section of the AMANOOGAWA-2SB $^{12}\text{CO}$ Galactic plane survey for comparison to the Planck CO($2 \rightarrow 1$) maps.

The area under scrutiny is shown in Fig. 14 for the AMANOOGAWA data set (top) and the Planck Type 1 CO [2–1] map (middle) at the working resolution of 15'. The correlation between the two data sets in given in the bottom panel and shows remarkable agreement with a best-fit value for the correlation of 0.95. Conversely to the $^{12}\text{CO}(1 \rightarrow 0)$ map, no $^{13}\text{CO}$ contribution was required to match the two data sets. This is once again in agreement to what was predicted in Sect. 6.2.2 where we found that the $^{12}\text{CO}$ contribution to the Type 1 $J = 1 \rightarrow 0$ line should be negligible, given the weighted bandpass transmission of the isotopologue in the 217 GHz channel. The residuals between the best-fit and the AMANOOGAWA data are found to be about 5%, which is compatible with the combined calibration uncertainties of Planck and AMANOOGAWA.

8.5. Comparison with the FIRAS CO $J = 1 \rightarrow 0$, $J = 2 \rightarrow 1$ and $J = 3 \rightarrow 2$ surveys

Fixsen et al. (1999) have analyzed a by-product of the Far Infrared Absolute Spectrophotometer (FIRAS on COBE launched in 1989) sky maps, namely integrated velocity maps of well-known Galactic lines. These include carbon, nitrogen and water lines, but, more importantly for the present study, the complete $^{12}\text{CO}$ rotation ladder. These are absolutely calibrated all-sky measurements. FIRAS has a better spectral resolution (13.5 GHz) than Planck-HFI but a much lower angular resolution. FIRAS integrated CO lines are retrieved from the Lambda website\footnote{http://lambda.gsfc.nasa.gov}. The first three transitions at 115.27, 230.54 and 345.80 GHz come from the low frequency emission line maps. They are converted from nW m$^{-2}$ sr$^{-1}$ to K km s$^{-1}$ with the coefficient $10^{-12}$ cm$^{-2}$/2K km s$^{-1}$. Error maps are processed in the same way and we neglect gain uncertainties.

Planck CO maps are convolved with the FIRAS beam in the same way as described in Appendix A of Planck Collaboration VIII (2014) and compared to FIRAS line maps within the FIRAS pixelization scheme. This is simply done by taking the Planck value at the grid point nearest to the FIRAS pixel within 15'. Uncertainties are much larger for FIRAS than Planck; the noisiest FIRAS values are not kept in the comparison. The cut-off is chosen as 160, 11 and 7 K km s$^{-1}$ for the CO($1 \rightarrow 0$), CO($2 \rightarrow 1$), and CO($3 \rightarrow 2$) lines, respectively. The FIRAS Galactic centre values may not be reliable because of the large velocity spread and we therefore discard any pixels within 4' of the Galactic centre. There is no possible tuning in this straightforward comparison.

Figure 15 shows the correlation plot between the Type 1 Planck CO data and the FIRAS $J = 1 \rightarrow 0$ (top), $J = 2 \rightarrow 1$ (middle) and $J = 3 \rightarrow 2$ (bottom) data. In each panel, the dashed blue line corresponds to perfect correlation ($y = x$), while the orange line gives the best fit. We find that FIRAS and Planck all-sky CO data are consistent with a linear relationship. For the CO($1 \rightarrow 0$) line, Fixsen et al. (1999) claim a detection only in the Galactic centre. With Planck we obtain a statistical detection of CO($1 \rightarrow 0$) with FIRAS outside the Galactic centre at the 7σ level. For the two other lines, FIRAS measurements tend to overestimate the CO emission with respect to Planck by at most 10%. This is well within the absolute calibration error for Planck and beam uncertainties for FIRAS.

8.6. Comparison with HARP/ACSIS CO $J = 3 \rightarrow 2$ data

Surveys in of the CO($3 \rightarrow 2$) transition are not as numerous as those of lower transitions, which makes assessing the quality
of the TYPE 1 $J = 3 \rightarrow 2$ map more difficult. We used part of the JCMT HARP/ACIS $^{12}$CO($3 \rightarrow 2$) Galactic plane data (soon to be published). Details on the HARP/ACIS system and calibration can be found in Buckle et al. (2009); Polychroni et al. (2012).

We use a $2^\circ$ long section of the Galactic plane from $l = 12.5$ to $l = 14.5$ where the survey has latitude range $\pm 0.5^\circ$. The original HARP data were not clipped at some $n\sigma$ threshold but collapsed over the whole spectral range, after performing a heavy smooth on all regions with signal less than $3\sigma$. This ensures there is no significant emission missing, while minimizing the addition of noise. The data were then smoothed to about the $4/5$ resolution, to mimic the Planck resolution but with pixels of around $5''$. The two maps were then brought down to the same pixelization, the least constraining rebinning resulting in a $43 \times 23$ pixels patch, with about 2,77 pixels. Because of the noise level inherent to the TYPE 1 map, a large dispersion is seen when simply performing the correlation between all pixels of these two patches. Therefore, we perform another rebinning, collapsing the latitude dimension to get a 43-point “average” longitudinal profile of the two maps. The correlation of these two profiles is plotted in Fig. 16.

Despite our rebinning, the correlation remains quite noisy, but the figure shows that the perfect correlation ($y = x$) line is a fair representation of the data when ignoring the two outliers. More data would be required to perform a thorough characterisation of the TYPE 1 $J = 3 \rightarrow 2$ map.

8.7. High Galactic latitude structures

In order to achieve a deep, high-Galactic-latitude statistical comparison of the Planck CO maps with ground-based observations, we use the observations performed at CfA and described in Hartmann et al. (1998) (HMT98) and Magnani et al. (2000) (MHHST00) for the North and South Galactic hemisphere respectively. These data consist of 8' beam observations of the $|b| > 30'$ sky, on a regularly-spaced grid, observable from Cambridge (MA). In total, 10,443 points in the north Galactic

![Fig. 14. Comparison of the Planck $J = 2 \rightarrow 1$ TYPE 1 CO map to the AMANOGAWA-2SB Galactic plane survey. From top to bottom we display the AMANOGAWA data, the TYPE 1 data in the same region and the correlation between the two maps. The log colour scale represents the number of pixels in a given intensity bin. The solid orange and dashed blue lines represent perfect correlation ($y = x$) and the best linear fit, respectively. The best-fit slope and intercept are $0.941 \pm 0.001$ and $0.792 \pm 0.009$, respectively.](image)

![Fig. 15. Comparison of the TYPE 1 Planck CO maps with the FIRAS $J = 1 \rightarrow 0$ (top), $J = 2 \rightarrow 1$ (middle) and $J = 3 \rightarrow 2$ (bottom) data. The solid orange and dashed blue lines represent perfect correlation ($y = x$) and the best linear fit, respectively. The best-fit slopes and intercepts are: a) $0.98 \pm 0.17$ and $0.33 \pm 0.65$; b) $1.12 \pm 0.02$ and $-0.01 \pm 0.04$; and c) $1.13 \pm 0.03$ and $0.04 \pm 0.02$.](image)
Fig. 16. Correlation plot between the latitude-collapsed longitudinal profiles (see text for details) of TYPE1 J = 3 → 2 HFI CO map and the HARP J = 3 → 2 survey. The solid orange and dashed blue lines represent perfect correlation (y = x) and the best-fit, respectively.

Fig. 17. Comparison of the Planck CO(1 → 0) maps with the high Galactic latitudes CO detections and non-detections from MHHST00. Top: correlation between the CO detections in MHHST00 and the Planck TYPE 2 and TYPE 3 maps. The latter was first smoothed to 15′. Bottom: distribution of all Planck CO(1 → 0) maps (at 15’ resolution) at the non-detection positions of MHHST00. The width of the distribution is compatible with the noise in the maps. Differences with respect to the values in Table 3 can be explained by the inhomogeneities of the noise in the Planck maps.

hemisphere and 4934 in the south were observed. A detection threshold of 0.3 K km s\(^{-1}\) (3σ) was considered. In total 26 detections were reported in the North and 133 in the South.

First, for each of these detection points, we compute the corresponding Planck TYPE 2 and TYPE 3 CO [1–0] fluxes (in a 10′ diameter disc). The TYPE 1 map was not selected for this analysis as its noise level makes it unsuitable for high Galactic latitudes. The top panel in Fig. 17 shows the correlation of the Planck TYPE 2 and TYPE 3 fluxes as a function of the 159 HMT98 and MHHST00 fluxes. A reasonable agreement and compatible absolute calibration is reached in these faint CO-emitting regions. The bottom panel presents the histogram of all three types of Planck CO maps fluxes at the 15218 locations where no detection is expected from the CFI surveys. The Gaussian distributions obtained are all centred on zero and have a standard deviation compatible with the noise level of the map. Discrepancies with respect to the values in Table 3 can be explained the inhomogeneities of the noise in the Planck maps. This comparison to the HMT98 and MHHST00 highlights the high quality of the Planck CO maps in the faintest CO regions.

9. Conclusions

The Planck-HFI maps contain a non-negligible component that is attributed to the emission, in the HFI spectral bands, of the three first CO rotation transitions coming from the interstellar medium. Several component separation methods are used to isolate this component from the others (CMB and diffuse Galactic emission, mainly thermal dust), by using the spectral diversity and large coverage of Planck-HFI.

This paper presents all-sky maps of the velocity-integrated emission of CO in the J = 1 → 0, J = 2 → 1, and J = 3 → 2 transitions. Three different types of maps are produced: i) Type 1 maps obtained from a single-channel analysis for the three transitions; ii) Type 2 maps available for the first two transitions only and coming from a multi-channel analysis; and iii) a single Type 3 map relying on a multi-line approach.

We have characterized the maps in terms of resolution, noise and systematic effects by cross-comparison and internal validation of the maps. Comparison to external CO data was also performed and general agreement found, always within the estimated calibration uncertainties of the data. Note however that the Type 1 J = 3 → 2 map could not be as thoroughly tested as the others because of the few external CO(3 → 2) data sets available.

In summary, TYPE 1 maps are the noisiest but suffer from the least systematic errors and other sky emission contamination. The Type 2 CO products provide high S/N single-line maps at the price of larger systematics and other sky emissions contamination, and are of lower resolution. Finally, the Type 3 map gives a high S/N and high resolution CO map but relies on the assumption of constant line ratios across the sky. Both Type 2 and Type 3 maps are more suitable for a use at intermediate and high-Galactic latitudes. The Type 1 maps are, by contrast, more reliable in terms of contamination by other sources of emission in the Galactic plane and on high CO intensity regions. In all these maps the \(^{13}\)CO contribution is not corrected and needs to be accounted for in any further scientific analysis.

The Planck CO maps are used within the Planck collaboration for the definition of regions of the sky where CMB, thermal SZ and cosmic infrared background cosmological studies can safely be performed. The Planck CO maps presented in this paper are delivered as part of the Planck nominal mission public archive.

Appendix A: Description of the Planck CO products

The characteristics of the released maps are the following. We provide HEALPix pixelization all-sky maps with $N_{side} = 2048$. For one transition, the CO velocity-integrated line signal map is given in K km s$^{-1}$ units at the CO transition frequency. A conversion factor from this unit to the native unit of HFI maps ($K_{CMB}$) is provided in the header. Four maps are given in a single file per transition (1–0), (2–1) and (3–2) and per TYPE 1, TYPE 2, and TYPE 3,

- a CO signal map;
- a CO null test map;
- a standard deviation map; and
- a mask for which a value of 1 corresponds to a valid pixel.

TYPE 1 products have the native HFI resolution 9′65, 4′99 and 4′82 for the CO [1 → 0], [2 → 1] and [3 → 2] transitions respectively. TYPE 2 products have 15′ resolution and are given for the two first transitions. The TYPE 3 product has a 5′5 effective resolution and corresponds to a combined map of the three CO transitions normalized at the $(J = 1 \rightarrow 0)$ transition frequency. These maps are shown in the left column of Figs. 3–5. The corresponding standard deviation maps are displayed in the right column.

Appendix B: Validation of CO extraction methods on simulations

Planck component separation methods (see Planck Collaboration XII 2014) are generally validated using the FFP6 set of simulations (Planck Collaboration 2013), which aim at providing a complete realization of the Planck mission. They rely on the Planck Sky Model (PSM) fully described in Delabrouille et al. (2013). FFP6 maps can be used for the multi-channel and multi-line approaches, but they do not provide the individual bolometer maps required to validate the single-channel CO extraction method. For the latter, CO-tailored simulations are needed, as described below.

B.1. Single-channel approach: Type 1 maps

We use here specific simulations of the Planck bolometer maps at 100 GHz. For each bolometer in the Planck 100 GHz channel, we construct a map of the sky emission considering CMB and other sources of sky emission (Galactic diffuse emission from synchrotron, thermal dust and free-free, and Galactic and extragalactic point sources). We use the same PSM model as for the FFP6 simulations (see below for a detailed description). For the CO emission we just use the Dame et al. (2001) map as a template and applied the CO bandpass conversion coefficients from Table 2 to convert to $K_{CMB}$ units. The per bolometer null maps were added to account for the noise contribution. The MILCA algorithm was then applied to these maps to reconstruct the CO signal using the single channel approach discussed in Sect. 4.2.1. We found that when the 12CO conversion coefficients are perfectly known the CO emission is well reconstructed. The contribution from contaminants was estimated to be less than 0.5% of the CO signal overall and the rms of the residuals consistent with the noise at about the 1σ level.

We also tested the sensitivity of the MILCA algorithm to uncertainties on the CO conversion coefficients. These uncertainties translate into noisier final CO maps and an overall calibration bias. For 1% and 5% uncertainties on the CO conversion coefficients we observe a combined signal to-noise-reduction of 6% and 60%, respectively.

B.2. Multi-channel approach: Type 2 maps

The multi-channel approach may be validated using Planck FFP6 channel intensity maps. Relevant to our purpose here, includes in particular a ν$^{-2.14}$ free-free emission component, a two-component dust emission from model 7 of Finkbeiner et al. (1999), and CO emission using the CO map of Dame et al. (2001) as the template.

We apply the multi-channel CO extraction method described in Sect. 4.2.2 to the set of FFP6 intensity maps and characterize the reconstructed CO(1 → 0) map with the input map of the FFP6 simulations. As for some of the other tests done throughout this paper, the comparison is performed in the Orion, Taurus, and Polaris molecular clouds.

A linear correlation ($CO_{type2} = a CO_{FPP6} + b$) between the two maps is found in the three regions, with slopes of 0.99 ±0.01, 1.01 ± 0.001, 0.999 ± 0.002 for Taurus, Orion, and Polaris respectively. We also checked the standard deviation of the residual maps $CO_{FPP6} - CO_{type2}$ against the average σr in each region obtained from the TYPE 2 CO(1 → 0) standard deviation map (see Fig. 3). In Polaris, the residual is within the ±1σ level, while it is at about 1.5σ for Taurus and Orion. In these two latter regions, the slightly poorer behaviour of the residual is attributed to the simple modified blackbody dust modelling of the multi-channel approach & that cannot properly capture the dust of the FFP6 simulations. With these caveats, the multi-channel approach is successfully validated on FFP6 simulations.

B.3. Multi-line approach: Type 3 map

The quality of the reconstruction of the TYPE 3 CO map was also validated using the FFP6 simulations. As described in Sect. 4.2.3, the TYPE 3 CO map is a byproduct of the CMB oriented component separation procedure and therefore, validation on simulations is presented in the companion CMB-oriented component separation paper Planck Collaboration XII (2014).
